# Introduction

The flow of water in the rivers and streams of Illinois provides a number of valuable uses. In many locations, it provides for the withdrawal of water for use in public and industrial water supplies. Also of great importance are instream uses of water, i.e., water used or needed within the stream channel, including flows for aquatic habitat and biodiversity, assimilation of wastewaters, water-based recreation, and stream aesthetics, as well as hydropower generation and navigation on the largest rivers. A planning and management goal for surface water resources in a watershed is to maintain sufficient streamflow for both instream needs and withdrawals (i.e., offstream needs). Planning also requires estimates of sustainable yields for streams and lakes to determine whether available resources will satisfy existing and future water needs during drought periods.

Water resource management requires an understanding of the quantity and frequency of streamflow within a river's watershed and the effects of various potential water use practices on the flow characteristics. The impacts of various natural and human factors, such as climate, land and water use, and hydrologic modifications, must also be analyzed as they can greatly affect the quantity, quality, and distribution (both in space and time) of surface waters in a watershed. Estimates of streamflow frequency and climatic and human impacts on streamflows can be useful for:

- Assessing water availability and public water supply system yields.
- Evaluating instream flow levels.
- Providing streamflow estimates for water quality analyses and regulations.
- Classifying Illinois streams by their hydrologic character for use in watershed management.

There are about 5145 miles of rivers and streams in the Little Wabash River basin. Roughly 100 rivers and streams with drainage areas in excess of 10 square miles account for 1640 of these stream miles. The flow character of these rivers and streams is monitored by streamgaging stations, which measure the flow of water over a period of time, providing information on the amount and distribution of surface water passing the station. Because it is not feasible to monitor all streams in a basin, gaging stations are established at selected locations, and the data collected are transferred to other parts of the watershed by applying hydrologic principles. Currently, there are four active streamgages in the basin, and seven locations in the watershed that have been gaged over the past 90 years. This report describes the hydrologic principles used to estimate the flow characteristics at these gages and the remaining ungaged locations within the Little Wabash River basin.

### **Background Information**

The Illinois Streamflow Assessment Model (ILSAM), a watershed management information tool, was designed to provide managers and planners with needed estimates of the streamflow frequencies along major streams within a watershed of interest. For the purposes of this model, major streams are those that have upstream contributing drainage areas that exceed 10 square miles in size. The ILSAM specialized software program was developed for use on a personal computer to provide estimates of the long-term expected magnitude and frequency of streamflow for any stream location. The effects of potential or hypothetical water resource projects on the quantity of water in streams also can be examined using options available in the model. With the completion of this study, the sets of hydrologic data used by the model have been developed for five major watersheds in Illinois: the Sangamon, Fox, Kaskaskia, Kankakee, and Little Wabash River watersheds. Hydrologic data sets are also currently being developed for the Rock River watershed.

### **Basic ILSAM Hydrologic Concepts**

The characteristics of streamflow in any watershed will, over time, vary from earlier conditions because of the cumulative impact of human activities in the region. Like most locations in Illinois, the Little Wabash River basin has experienced considerable land-use modification since European settlement, including cultivation, drainage modification, removal of wetland areas, and deforestation. Most of these modifications occurred in the late 1800s, prior to the introduction of streamgaging activities in the region, and thus the existing gaging records cannot reflect the impact of these changes. Most of the land in the watershed remains in agriculture, much as it did almost 100 years ago. Urbanization has affected only a very minimal percentage of land in the Little Wabash River basin.

For watersheds without major hydrologic modifications, climate variability has the greatest influence on the changes in streamflows. Trend analysis of streamflow records throughout many areas of Illinois suggests that the influence of climate variability is usually large enough to mask the impacts of less obtrusive watershed modifications to river flows, including many contemporary land-use changes other than urbanization. However, modifications to the watershed, such as the construction of reservoirs and channel dams, stormwater detention facilities, water-supply withdrawals, and wastewater discharges to the streams, have had readily definable impacts on the streamflows.

For this analysis, the flow in a stream can be separated into two components: 1) the unaltered or "virgin" flow conditions as influenced primarily by weather and climate phenomena as well as the topography, hydrogeology, and prevailing land-use conditions in the watershed, and 2) modifications to the flow conditions by human activity that produced a quantifiable change in the temporal response of flow from the watershed. Modifications to the flow conditions to a subtractions from the flow in the stream, such as from effluent discharges or water-supply withdrawals, or large changes in the water stored within the watershed, such as might be caused by a major reservoir. The evaluation of flow modifications is limited to water resource projects that can be objectively evaluated using existing data, and whose impact on present flow conditions can be differentiated from the expected character of the unaltered flow condition.

Streamflow varies considerably over time, not only displaying day-to-day fluctuations as influenced by weather phenomena, but also by climatic variations that may cause streamflows to remain above or below the long-term expected condition for several decades. The climate during the period for which streamflow records are available also significantly influences our perception and calculation of the expected characteristics of streamflow. Therefore, the estimation of long-term streamflow conditions spanning several decades is necessary to smooth out the impacts of climate variability.

Complete descriptions of the methods used to determine the streamflow characteristics for the ILSAM have been presented in several earlier reports (Knapp, 1988, 1990, 1992), and rather than repeating their descriptions, the reader is referred to these earlier studies. This report focuses on the development of the data used for ILSAM application to the Little Wabash River Basin watershed.

# Streamflow Information Produced by ILSAM

The ILSAM produces information on 154 selected streamflow parameters, including flow duration relationships (flow versus probability of exceedence) and low flows for various durations and expected recurrence intervals. All flows are given in units of cubic feet per second (cfs). The 154 flow parameters are described in detail in the following paragraphs. For gaging locations, these flow parameters are computed using daily flow records, which are average flow rates estimated for each individual day within the gage's period of record.

#### Average Flow Values

Parameters: Average Annual Flow (Qmean) and Average Monthly Flows

# Annual Flow-Duration Values

Description: The 2 percent flow  $(Q_2)$ , for example, is the daily streamflow rate that is exceeded on exactly 2 percent of the days. The 1 percent flow  $(Q_1)$  is necessarily a higher flow rate because it is exceeded less frequently.

Parameters: Q1, Q2, Q5, Q10, Q15, Q25, Q40, Q50, Q60, Q75, Q85, Q90, Q95, Q98, and Q99.

### Monthly Flow-Duration Values

Description: Monthly flow duration values are defined in the same manner as the annual flow-duration values, except that they are determined using only those daily discharges that fall within a certain month of the year.

Parameters for each calendar month: Q<sub>2</sub>, Q<sub>10</sub>, Q<sub>25</sub>, Q<sub>50</sub>, Q<sub>75</sub>, Q<sub>90</sub>, and Q<sub>98</sub>.

#### Low Flows

Description: Each low-flow parameter is defined by a duration in consecutive days and a recurrence interval in years. A 7-day low flow for a given year is the lowest average flow that occurred within a 7-day consecutive period during that year. The 7-day, 10-year low flow is the 7-day low flow that occurs on average only once in 10 years. A 2-year low flow is the value expected to occur during an "average" year.

Low-Flow Durations: 1, 7, 15, 31, 61, and 91 days

Recurrence Intervals: 2, 10, 25, and 50 years

# Drought Flows

Description: Drought flows are similar to low flows, except that the duration of the period is longer and is defined in months instead of days, and the average low flows are developed from monthly records. Drought durations are usually not defined on an annual basis, because a drought period typically encompasses multiple years.

Drought Flow Durations: 6, 9, 12, 18, 30, and 54 months

Recurrence Intervals: 10, 25, and 50 years

# Database Used by ILSAM

The ILSAM uses four basic sets of data for computing streamflow characteristics in a watershed.

- Estimates of the 154 flow parameters at gaging stations within the watershed. Streamflow frequency estimates are also computed and entered into the database for other locations in the watershed where such computations are useful to the operation of the model, such as locations downstream of reservoirs or upstream and downstream of major river confluences. Appendix A lists this basic streamflow frequency data for 35 watershed locations.
- 2) A data set of all flow modifiers in the watershed (withdrawals, diversions, and effluent discharges). This includes the estimated impact of that modification on each of the 154 flow parameters produced by the model. Appendix B lists the basic flow data for these modifications.
- 3) A table of watershed characteristics for 804 locations in the basin, including stream mileage, drainage area, soils information, and the location of gaging stations, water use projects, reservoirs, and other points of interest in the basin. Appendix C lists this stream network data.
- 4) The set of regional regression equations used to estimate the virgin flow conditions for each of the 154 flow conditions for ungaged sites in the watershed. Appendix D presents these equations.

In addition to these four basic sets of data, three supplemental data sets provide stream codes that help to identify each stream in the watershed, an index of the stream network in the watershed (which helps the model identify all downstream locations affected by a flow modification), and basic data on the size of each major reservoir in the watershed. All data sets have been imported into a Microsoft Access database for access directly by the ILSAM.

# Acknowledgments

This material is based upon work supported by the Illinois Department of Natural Resources, Office of Water Resources (IDNR-OWR), under Award No. IDNR WR09803. Support also was provided by the Illinois State Water Survey (ISWS), a Division of IDNR. Gary Clark of IDNR-OWR served as project liaison. The study was conducted under the general supervision of Mike Demissie, head of the ISWS Watershed Science Section. Other ISWS staff assisted in the preparation of this report. Eva Kingston edited the report, Kathy Brown prepared the maps, and Linda Hascall reviewed the figures.

The Illinois Environmental Protection Agency and the U.S. Geological Survey provided wastewater effluent data and streamgaging records, respectively.

Any opinions, findings, and conclusion or recommendations expressed in this report are those of the authors and do not necessarily reflect those of the Office of Water Resources or the Illinois State Water Survey.

# **Description of the Little Wabash River Watershed**

The Little Wabash River watershed is located in the southeastern portion of Illinois and has a total area of approximately 3238 square miles. The watershed is located in portions of 15 counties, as shown in figure 1. The headwaters are located in Coles County southwest of Mattoon, and the river generally flows south to southeast until its confluence with the Wabash River at the southern tip of White County near New Haven, Illinois. The total length of the Little Wabash River is approximately 239 miles. The nine largest tributaries to the Little Wabash River are the Skillet Fork, with a drainage area of 1059 square miles (mi<sup>2</sup>), Big Muddy Creek (316 mi<sup>2</sup>), Elm River (278 mi<sup>2</sup>), Fox River (205 mi<sup>2</sup>), Main Outlet (179 mi<sup>2</sup>), Horse Creek (104 mi<sup>2</sup>), Auxier Creek Drain (101 mi<sup>2</sup>), and Salt Creek (94 mi<sup>2</sup>). Figure 2 shows the locations of these major streams.

The following sections describe the physical characteristics of the Little Wabash River watershed, which are useful for understanding the surface water hydrology of the watershed. The reader is also referred to a previous study (Barker et al., 1967) for a more comprehensive description of the watershed.

# Watershed Physiography and Soils

Most of the Little Wabash River watershed lies within two distinct physiographic regions as identified by Leighton et al. (1948): the Springfield Plain, and the Mt. Vernon Hill Country. Much of the northern third of the Little Wabash River watershed falls within the Springfield Plain covering Effingham and Jasper Counties, the northern half of Clay County, and the southern half of Shelby County. This area was covered by the Kansan Period of glaciation, and is distinguished by its relative flatness and the shallow entrenchment of its drainage. The Mt. Vernon Hill Country covers the southern two-thirds of the watershed, and represents that area covered by the older Illinoian period of glaciation. It is characterized by developed topography and low relief, with a mature drainage system. Most streams have broad valleys with upland areas that have better drainage than the larger valley bottoms. (Leighton et al., 1948).

Less than 3 percent of the watershed falls within the Bloomington Ridged Plain, which covers much of central Illinois, and is associated with land that was covered by the most recent Wisconsin Period of glaciation. The Shelbyville moraine and its outwash plain, which cross the northern tip of the Little Wabash River watershed in Coles and Shelby Counties, represent the southernmost extent of the Bloomington Ridged Plain.

#### Land Slopes

The elevation of the watershed ranges from a high of approximately 780 feet above the National Geodetic Vertical Datum (NGVD), about 2 miles south-southeast of Mattoon, to a low of approximately 330 feet NGVD where the Little Wabash River meets the Wabash River. Table 1 provides the average distribution of overland slopes for the two major physiographic regions in the Little Wabash River watershed. The overland slopes listed in this table were estimated from data in Runge et al. (1969). Almost two-thirds of the land in the Springfield Plain is nearly level, having less than a 2 percent slope. An additional 20 percent of the land in the region is gently sloping with the remaining 17 percent of the land

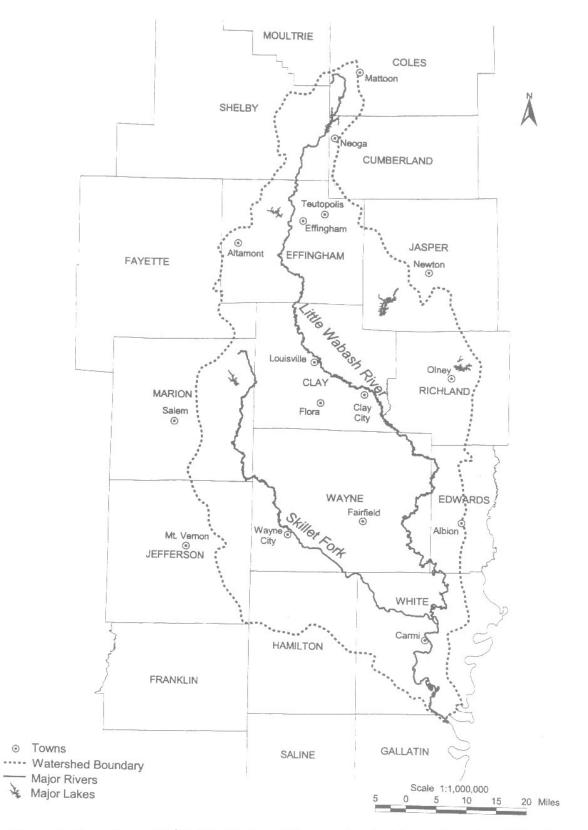

Figure 1. Location of the Little Wabash River watershed in southeastern Illinois

# Table 1. Distribution of Overland Slopes in Physiographic Regionsof the Little Wabash River Watershed

Overland slope (%)	Slope description	Springfield Plain	Mt. Vernon Hill Country
0 - 2	Nearly level	63.0	56.0
2 - 4	Gently sloping	20.0	20.0
4 - 7	Moderately sloping	4.3	9.7
7 - 12	Strongly sloping	4.1	8.0
12 - 18	Moderately steep	1.5	3.8
18 - 30	Steep	7.1	1.4
> 30	-	0.0	1.1

Percentage of land area

Note: Overland slopes were estimated from data in Runge et al., 1969.

being moderately sloped to steep (slopes of 4 to 30 percent). The Mt. Vernon Hill Country is a more mature, rolling topography having both fewer flat areas and fewer steep slopes than the Springfield Plain.

### **Channel Slopes**

The slope of the Little Wabash River increases from downstream to upstream. From the mouth of the Little Wabash River to the town of Golden Gate, River Mile 76, the slope is a mild 0.4 feet per mile. The average slope from Golden Gate to Effingham increases to 1.2 feet per mile. At Effingham the slope is roughly 3 feet per mile, and from Effingham upstream to the headwaters of the Little Wabash, the slope is 7.3 feet per mile. The Little Wabash River valley, which generally coincides with pre-glacial bedrock valleys (Barker et al., 1967), widens from about  $\frac{1}{2}$  mile wide near the upstream reach of the watershed to 2 miles wide near the mouth.

Table 2 provides examples of channel slopes for tributaries in the Little Wabash River watershed. The slope for most smaller tributaries is from 6 to 20 feet per mile. As the size of the stream and its drainage area increases, the channel slope decreases to 2-5 feet per mile for most of the larger tributaries in the watershed. These slopes are typical for many streams throughout Illinois.

# Soil Types and Their Influence on Streamflow Hydrology

Soils in the Little Wabash River watershed are characterized by generally poor drainage and moderately low permeability. The surface permeability of most soil types is generally less than 2 inches per hour with subsurface permeabilities often less than 0.6 inches per hour. Upland soils, such as the Hoyleton-Cisne soil associations, are on nearly level land and often have the lowest subsurface permeabilities in the region, less than 0.2 inches per hour. Hillslope soils, such as those belonging to the Ava-Bluford-Wynoose soil association, often have subsurface soil permeabilities in the range of 0.2 to 0.6 inches per hour.

Figure 2. Location of major streams, lakes, and gaging stations in the Little Wabash River watershed

	Drainage area

Salt Creek	5.8	5.5	
Skillet Fork	13.5	3.5	2.6
<b>Note:</b> = not applicable			

# Table 2. Examples of Channel Slopes in the Little Wabash River Watershed (ft/mi)

Bottomland soils, such as the Belknap-Bonnie-Petrolia association, have somewhat higher subsurface permeabilities in the range of 0.6 to 2.0 inches per hour.

Soil type and permeability are of considerable importance in the evaluation of watershed hydrology because they have a great influence on the rainfall-runoff process and the eventual distribution of flow to the stream. For example, soils with high sand content generally allow a much higher proportion of precipitation to infiltrate the soil. This reduces the amount of water flowing overland directly to the stream and thereby reduces the rate of storm runoff. A large portion of the water that infiltrates is usually stored as shallow groundwater and may be discharged to the stream after the storm, later the same year, and even in following years whenever there is a large accumulation of subsurface moisture. The presence of sandy material in the subsoil and shallow groundwater to the stream). In contrast, areas where soils have high clay content usually have greater runoff during storm periods, and less groundwater is contributed to streamflow during dry periods. Much of the soil in the Little Wabash River basin is representative of this latter group, with low soil permeability producing a large variability in runoff.

The ILSAM uses estimates of the subsoil permeability to compute the streamflow characteristics from a given watershed. County soil surveys provide the most useful information for characterizing the subsoil permeability within the watershed. For each soil type, the permeability of the lowest soil layer is used to estimate the subsoil permeability. If, for example, the permeability of the lowest soil layer is listed in the range of 0.2-0.6 inches per hour, an average value of 0.4 is used as the permeability for the subsoil. Weighted average values are then computed for each soil association in the county.

Five modern (post-1960) county soil surveys are applicable to the Little Wabash River watershed: surveys for Coles, Effingham, Hamilton, and Jasper Counties, and the joint survey for Edwards and Richland Counties. Table 3 gives the subsoil permeability for each

County	County soil association	County area, percent	Average subsoil permeability	Permeability Range

# Table 3. Soil Associations and Subsoil Permeability from Post-1960 County Soil Surveys

soil association within these county surveys. For the remainder of the watershed, the best available coverage of soil characteristics is provided by the statewide soil association map (Agricultural Experiment Station, 1982), which is also available in a geographic informations system (GIS) coverage. State soil associations are generally similar to, but not the same as the county soil associations, which deal more specifically with the soil types within that county. For each state soil association, the subsurface soil permeability is estimated as the regional average of the permeability from similar soil associations within the individual county soil surveys.

~	Average subsoil	Permeability

# Table 4.State Soil Associations and Estimated Subsoil Permeability<br/>for Little Wabash River Watershed

**Note:** Average subsoil permeability for a specific state soil association is estimated using permeability values given in county soil surveys for counties in and near the Little Wabash River watershed. These values are not necessarily representative for that soil association in other regions in the State.

Table 4 lists the computed regional permeability for each of the state soil associations within the Little Wabash River watershed. An alternative method uses the subsurface soil permeabilities that are provided in the State Soil Geographic (STATSGO) data for Illinois, developed by the Natural Resources Conservation Service (NRCS) of the U.S. Department of Agriculture.

### **Reservoirs in the Little Wabash River Watershed**

The Little Wabash River watershed contains 15 artificial reservoirs that have a storage capacity in excess of 300 acre-feet. Table 5 lists these reservoirs, and figure 2 shows the locations of the five largest reservoirs. Newton Lake, the largest lake in the watershed was built as a cooling lake for the Central Illinois Public Service (CIPS) electricity-generating plant near Newton. All but one of the remaining reservoirs in the watershed with a storage capacity of more than 1000 acre-ft are used for public water supply. Some smaller lakes are also used for this purpose, and many others are used for conservation or recreational purposes. All the lakes listed in table 5 were created by the impoundment of streams, with the exception of Goose Pond, which is a natural lake.

Reservoir	County	Major purpose	Surface area (acres)	Storage (acre-ft)
Newton Lake	Jasper	Cooling	1650	28500
Lake Mattoon	Shelby	PWS	988	11820
East Fork Lake	Richland	PWS	672	12460

### Table 5. Major Reservoirs in the Little Wabash River Watershed

**Note:** PWS = Public Water Supply

# Low Channel Dams

Five low channel dams, listed in table 6, have been built in the watershed of the Little Wabash River immediately downstream of public water supply (PWS) intakes. Two of these sites at Carmi and near Olney are no longer used for water supply. The low channel dams are located entirely within the river channel, typically with a height of 8 feet or less, and are used to pool sufficient water so that the pumps can operate during low flow conditions. In some cases, the water stored by these dams may be used as a supplemental supply of water during periods of little or no flow in the river.

# Hydrologic Budget

#### Precipitation

Twelve precipitation gages in and around the Little Wabash watershed have continuous records that date from before 1900 to the present. Table 7 lists these stations and their long-term (1895-1999) average annual precipitation. The average annual precipitation for the Little Wabash River watershed is roughly 42 inches, and varies from 44 inches in the southern portion of the watershed to approximately 39 inches along the northern edge. Of the stations listed, the Charleston, Olney, and McLeansboro records are the most complete and were selected to be representative of the northern, central, and southern portions of the watershed, respectively. Annual precipitations for Charleston, McLeansboro, and Olney are plotted for the years 1895-1945 (figure 3) and for the years 1945-1999 (figure 4). Also plotted in figures 3 and 4 are the long-term (1895-1999) average precipitation for each station and an 11-year moving average of the annual values. The 11-year moving average is used to remove a lot of the short-term variation in precipitation amounts, including the potential influence of sunspot activity that has an 11-year cycle. The middle year in the 11-year period is used as the plotting position in both figures.

The annual precipitation values in figures 3 and 4 illustrate the great variability of rainfall, not only year to year but also at different locations within the same watershed. The moving averages shown in figures 3 and 4 indicate several major wet and dry periods. All three locations experienced consistent below-normal precipitation for the period 1952-1965, as compared to the long-term average. The average rainfall for Olney and McLeansboro has been consistently above the long-term average since the early 1980s. Charleston experienced a period of high average rainfall during the 1970s, but since that time the average has fallen closer to the long-term average. The average annual precipitation for the entire watershed fell below 29 inches in four years, 1895, 1914, 1936, and 1953, with 1953 experiencing the lowest annual average precipitation of about 28 inches (14 inches below average). The two wettest years on record occurred in 1927 and 1945, with average annual watershed amounts of 56 inches and 62 inches, respectively.

# Table 7. Annual Average Precipitation for Long-Term Gages Located in and around the Little Wabash River Watershed

	Annual average		Annual average
Location	precipitation (inches)	Location	precipitation (inches)
Albion	44.4	Harrisburg	44.0
Casey	39.8	Mattoon	37.9
Charleston	39.1	McLeansboro	42.2
Effingham	39.7	Mt. Carmel	43.7
Fairfield	42.9	Mt. Vernon	41.6
Flora	40.8	Olney	41.9

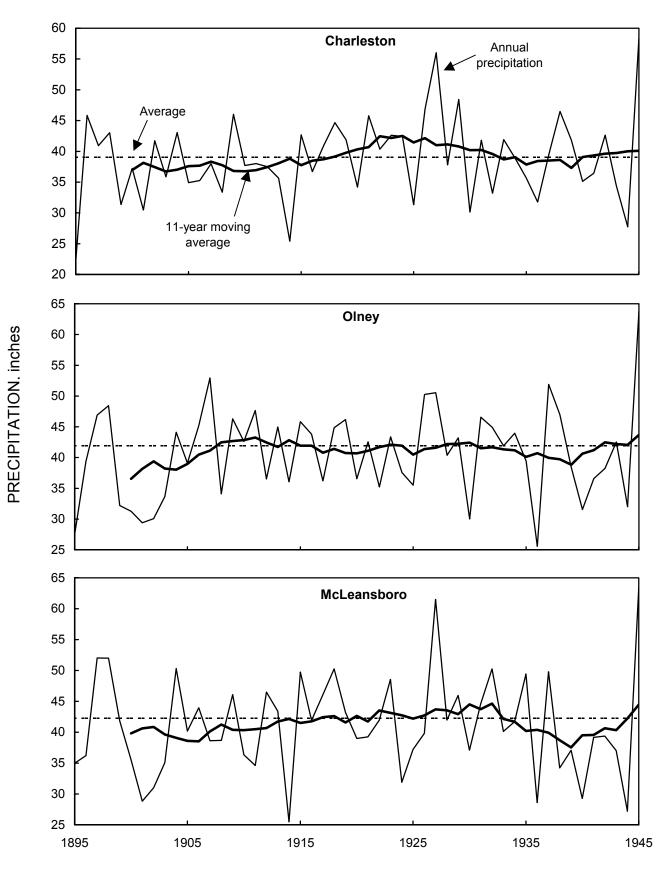

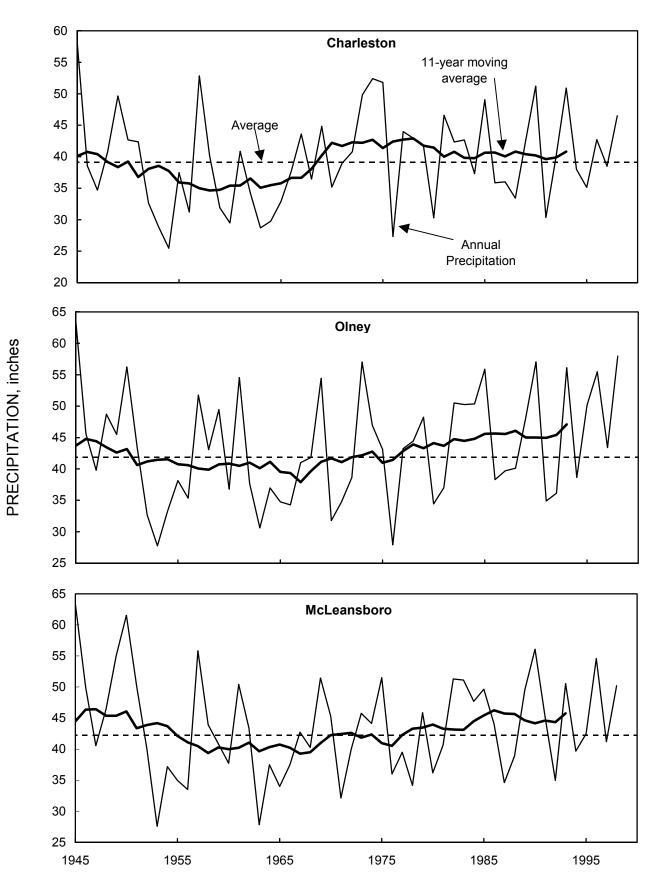

Figure 3. Annual precipitation at Charleston, Olney, and McLeansboro, 1895-1945

#### Evapotranspiration

A majority of the water that falls as precipitation is stored by the soil and eventually returns to the atmosphere through evapotranspiration (evaporation plus transpiration from plants). The average annual amount of evapotranspiration is roughly 30 inches, and ranges from 29 inches in the northern portion of the region to 31 inches in the southern portion. This average annual evapotranspiration amount, estimated from Knapp (1988), was computed as the difference between long-term average values of regional precipitation and streamflow using the methodology given by Jones (1966). Most of the water not used in evapotranspiration ultimately flows to streams by way of either runoff following precipitation events or from the more gradual seepage of water stored in the soil and shallow groundwater.

#### Monthly Water Budget

Table 8 shows a typical distribution of precipitation, evapotranspiration, and streamflow over the Little Wabash River watershed for each month of the year. The monthly values of precipitation and streamflow in table 8 are taken from available records, and the general monthly distribution of evapotranspiration was computed using the soil moisture component of a hydrologic model (Durgunoglu et al., 1987), with a slight adjustment to match the average annual evapotranspiration given by Knapp (1988). The sum of the evapotranspiration and streamflow do not equal the precipitation in any one month due to the effect of subsurface storage of water (soil and groundwater). For any one month, the average addition to this subsurface storage ( $\Delta$ S) is estimated as the remainder between the precipitation (P), the evapotranspiration (ET), and the streamflow (Q):  $\Delta$ S = P – ET – Q. The

Month	Р	ET	Q	$\Delta S$
January	2.9	0.2	1.3	+1.4
February	2.5	0.5	1.6	+0.4
March	4.0	1.6	2.0	+0.4
April	4.1	2.4	2.0	-0.3
May	4.5	3.5	1.6	-0.6
June	4.2	4.8	0.9	-1.5
July	3.5	5.9	0.5	-2.9
August	3.3	5.3	0.3	-2.3
September	3.4	3.1	0.1	+0.2
October	3.1	1.8	0.2	+1.1
November	3.4	0.8	0.5	+2.1
December	<u>3.1</u>	0.3	<u>1.0</u>	+1.8
TOTAL	42.0	30.0	12.0	0.0

# Table 8. Typical Monthly Distribution (inches) of Precipitation,Evapotranspiration, Streamflow, and Subsurface Storage

Note: P = precipitation, ET = evapotranspiration, Q = streamflow, and  $\Delta S = change$  in subsurface storage.

total streamflow (Q) is the sum of both direct runoff and the baseflow that originates from the subsurface storage.

Evapotranspiration is noticeably greater than precipitation during the height of the growing season (June through August) when the greatest reduction in subsurface water storage occurs. Lowest streamflow rates are expected near the end of the growing season (August through October) when soil moisture and groundwater are at their annual minimums. Average runoff is highest in February through May when the soil moisture is often near its annual maximum.

## **Population**

The Little Wabash River watershed is a predominantly rural watershed with a total population in 1999 of approximately 122,000. Table 9 gives the 1999 population for the 15 counties either partially or entirely contained within the Little Wabash River watershed. The population of the watershed fell by roughly 2 percent from 1980 to 1999. The Illinois Bureau of the Budget population prediction for 2020 suggests that the population in the watershed will rise approximately 4 percent over the next 20 years. The watershed has no major metropolitan areas. Only Effingham (12,254) and Mattoon (18,441) have populations of more than 10,000 in the watershed; however, Mattoon is only partially within the watershed. Olney (8873), Carmi (5626), Fairfield (5442), Flora (5093), Altamont (2296), and Albion (2116) are the only other cities that have populations of more than 2,000.

# Table 9. Population Data for the Little Wabash River Watershed Counties

*(in thousands)* 

# Notes:

Estimates of the population of each county within the Little Wabash watershed are based on data from the 1980 Census of the Population (U.S. Bureau of the Census, 2000a) and the Census Bureau's County Population Estimates for 1999 (U.S. Bureau of the Census, 2000b).

\* Population projections for counties are from the Illinois Bureau of the Budget (1990).

\*\*Population within the Little Wabash River watershed is given in parentheses.

# Water Use and Water Supply

#### Public and Industrial Water Supply

The average amount of water used for public water supply (PWS) in the Little Wabash watershed varies annually, but in the past 5 years it has usually been in the range of 11.5 to 12 million gallons per day (mgd). Average per-capita water use is approximately 94 gallons a day. Surface water resources supply roughly 80 percent of the total PWS, or about 9.5 mgd. Of this amount, approximately 6 mgd is supplied by reservoirs in the watershed, 3 mgd is supplied by withdrawals from the Little Wabash River and Skillet Fork, and more than 0.3 mgd is imported to the watershed from Rend Lake. The remaining 20 percent of the PWS in the watershed comes from ground-water sources. These water use estimates do not include domestic water use outside of the service areas of the public water supplies, nor do they include water used for livestock. These latter uses are most often supplied from ground-water sources.

Tables 10 and 11 list the major public water supply systems in the watershed. Most of these water supplies have experienced little or no increase in water use over the past 10 years. However, the Effingham PWS has seen water use increase 70 percent over the past 10 years, and Olney experienced a 20-percent growth in water use. A number of communities also have connected to the EJ Water Corporation, which in recent years has experienced significant growth in service population, and thus water use.

Surface water also provides cooling water for the CIPS power plant at Newton Lake. Water used at the power plant is recirculated back into the lake where it is cooled. The heat loading from the plant forces some additional evaporation from the lake surface. The amount of forced evaporation is expected to be roughly 1 percent of the total water withdrawn for cooling use, as estimated for similar cooling lakes in central and northern Illinois.

# Table 11. Public Water Supplies from Surface-Water Sources

**Note:** WD = Water District

The following paragraphs describe the history and current status of the largest PWS systems in the Little Wabash River watershed and those systems that obtain water from the Little Wabash River or Skillet Fork. Most of this information was taken from files at the Illinois State Water Survey, which contain reports documenting PWS systems since the early 1900s.

#### Altamont

The Altamont PWS, created in 1913, obtained its water from two wells. Over the next 20 years, additional wells were developed, but the capacity of each well was limited, and they became inadequate to meet the city's PWS needs. In 1935, an impounding reservoir with a storage of 33 million gallons (mg) was built on Second Creek, northeast of the city. During the 1953-1954 drought, the city experienced severe shortages, and water was piped to both Effingham and Altamont from the Embarras River, located 30 miles to the east. In 1973, the New Altamont Reservoir located southeast of the city was created with a capacity of more than 300 mg.

#### Albion

As early as 1912, there were investigations about establishing a PWS at Albion; however, the development of a nearby groundwater source was considered out of the question because of the high mineral content in the water. Eventually, in 1926, the city began withdrawing water from Bonpas Creek, located 4 miles west of the city. A low channel dam storing 18 mg helped supply the city during dry periods. There were some shortages during the 1953-1954 drought, and the city used a nearby shale pit for supplemental supply. By the late 1950s, the city was experiencing problems with high salinity in Bonpas Creek, and these water quality problems, not quantity, led the city to a new water supply source. In 1963, the city developed and began using 50-foot deep wells in the Wabash River lowlands, located 10 miles to the southeast near Grayville.

#### Carmi

The Carmi PWS system, established in 1894, obtained water from the Little Wabash River. In 1953, a 4.5-foot channel dam was built to increase the depth of water above the PWS intake. The river never failed to yield sufficient water for the city's use, to the extent that a 1954 newspaper headline proclaimed that "Carmi is an Oasis in the South Illinois Drought." But during low flows, the river water was hard and occasionally had high chloride levels. In 1974, the city changed its water supply to wells located in the Wabash River lowlands, 5 miles east of the city, to save money through reduced water treatment.

#### Clay City

The Clay City PWS system, established in 1938, obtains water from the Little Wabash River. The river has never failed to yield sufficient water for the city's use, even though shortages were experienced at other locations along the river during the drought of 1953-1954. The current water use of the city is approximately 100,000 gallons per day (gpd).

#### Effingham

The Effingham PWS was originally established in 1895 using the Little Wabash River as the sole source of water. A channel dam was constructed on the Little Wabash River when

the system was established or shortly thereafter. Following the drought of 1930-1931, the CIPS Service Lake was constructed to serve both as a settling pond and side-channel reservoir, providing storage during low flow periods. The CIPS Lake has an estimated capacity of 64 million gallons (Durgunoglu et al., 1990). During the drought of 1953-1954, the Effingham system experienced severe shortages. Water consumption during the drought was reduced by 50 percent of normal, down to 400,000 gpd, and water was pumped to the CIPS Lake from the Embarras River using an oil pipeline from the Newton area. This pipeline also provided water to the city of Altamont. In 1957, Effingham built Lake Sara, located several miles to the west of the city, to provide a supplemental source of water during droughts.

The Effingham PWS system is experiencing the greatest increase in water use in the Little Wabash River watershed, with the annual average water use increasing in the last 10 years from 1.4 million gallons per day (mgd) to 2.4 mgd. According to their water operator, the Little Wabash River supplies about 60 to 70 percent of the water, with Lake Sara supplying the remainder. Detailed pumping records are not kept. A gravity flow release from Lake Sara is used during low flow periods and during wet periods when the lake is overflowing. Lake Sara water is generally of better quality than the river water and is preferred when the release of water from the lake does not cause the lake level to decline.

## EJ Water Corporation

Over the last 10 years, a number of communities in Effingham, Jasper, and Clay Counties have connected to water supplied by EJ Water Corporation, which obtains its water primarily from shallow groundwater sources near the Embarras River in Jasper County. Several communities in the Little Wabash River watershed are currently serviced by EJ Water: Dieterich, Edgewood, Louisville, Mason, and Watson. The current water use of the EJ Corporation is roughly 0.5-0.6 mgd

### Fairfield

The Fairfield PWS system, established in 1926, obtains water from the Little Wabash River approximately 6 miles east of the city. During the 1954 drought, the city did not experience any water shortages; however, an earthen dam was placed in the river channel to retain as much water as possible. In 1972, a side-channel reservoir was constructed near the existing intake on the Little Wabash River, and now serves as the city's water supply source.

The reported water use of the city has decreased over the past 10 years, from past estimates of almost 1.0 mgd to recent estimates of 0.85 mgd. This reduction in estimated water use may be related in part to improved water metering rather than actual reductions in consumption. The side-channel reservoir has a reported capacity of 90 million gallons, roughly equivalent to a 106-day supply, given an average daily use of 0.85 mgd. There are two pumps at the withdrawal site, each sufficient to withdraw approximately 2000 gpm or almost 3 mgd. The side-channel reservoir is normally refilled daily. Based on the streamflow estimates produced by the ILSAM, it is believed that the low flows on the Little Wabash River combined with the storage in the side-channel reservoir may be able to support a water use of up to 2.5 mgd during a 50-year drought. The Fairfield water supply also services the New Hope Water District and the communities of Boyleston and Golden Gate.

#### Flora

The Flora PWS system, installed in 1911-1912, obtained its water from a number of wells. Even at that time, the yield of the wells was known to be inadequate for the full needs of the city. In 1933, a raw-water pumping station was built on the Little Wabash River, located 5 miles north of the city, which has served as the city's water supply since that time. Prior to the 1954 drought, the city had an average water use of 0.6 mgd, with consumption rising to almost 1 mgd during summer months. During the summer of 1954, the flow in the river was not sufficient to supply the city, and additional water was obtained by pumping water from various pools located along the river. In the fall of 1954, a channel dam was constructed downstream of the existing pumping station. At the time of construction, the channel dam was reported to have a storage capacity of 50 million gallons.

Flora currently has an average water use of 0.7 mgd. Broeren and Singh (1989) identified the Flora PWS system as having insufficient yield to provide water during a 50-year drought. Data produced by the present ILSAM study indicate that the flow in the Little Wabash River is sufficient during a 50-year drought to supply a withdrawal rate of only 0.5 mgd; however, this does not consider the possible use of water stored behind the channel dam.

Since the present amount of storage behind the channel dam is not known, it is not possible to determine whether the city could provide its current level of water use (0.7 mgd) during a 50-year drought. During the last 20 years, the city had proposed the development of a side-channel reservoir to supplement its supply; however, these plans are no longer being pursued. The city is now proposing to obtain its water from a new water supply system, which reportedly would obtain its water from Carlyle Lake.

### Louisville

Louisville established its water works on the Little Wabash River in 1899-1900. Until 1998, the city obtained its water from the river, but it has since shut down its water works and now obtains its water from the EJ Water Corporation. The only water shortage was experienced during the 1953-1954 drought. Flow in the river ceased during that drought, water use was restricted, and a bulldozer was brought in to build an earthen dam in the river and create a pool that provided sufficient water through the remainder of the drought. The average annual water use at Louisville is approximately 100,000 gpd.

### Mattoon

Paradise Lake was constructed in 1908 to provide a water supply for the city of Mattoon. Paradise Lake failed to provide sufficient water for the city during the drought of 1953-1954, and the city had to develop wells for a supplemental supply during that drought. A plan for piping water from the Kaskaskia River also was examined during the drought but the plan was never implemented. In 1957, Lake Mattoon was constructed, and, in combination with Lake Paradise, has continued to provide the city's water supply since that time. The current annual average water use of Mattoon is about 2.8 mgd.

#### Neoga

The Neoga PWS was established in 1915, and for the next 43 years the town obtained its water from two large-diameter shallow wells located in drift material. In 1958, an intake was built into the then newly constructed Lake Mattoon, which was located less than 2 miles

northwest of Neoga. The lake has remained the source of water for the town. The current annual average water use is approximately 140,000 gpd.

#### Olney

Olney first installed a PWS system in the early 1890s, obtaining water from a channel dam on the Fox River located 1.5 miles west of the city. An impounding reservoir, Vernor Lake, was built in 1924 on a small tributary to the Fox River. Severe water shortages were experienced in 1953 and 1954, water use was restricted, and a temporary pipeline was built to pump water from the Embarras River into the Fox River. A second reservoir, Borah Lake, was constructed in 1954 and had just begun filling up when the drought broke later that year. Heavy rainfall severely eroded the spillway of Lake Borah in 1970. Although repairs to the Borah Lake dam were made several year later, the new larger East Fork Lake was constructed in 1972 with a capacity of 300 million gallons, and has since served as the primary water supply for the city.

## Wayne City

Wayne City used private wells for its water supply until 1955, when a channel dam was constructed on the Skillet Fork to provide a sustainable source of water for the new PWS. A side-channel reservoir was constructed in 1972 to provide water during low flows and conditions when the river water quality was not desirable. Although the capacity of the side-channel reservoir is not known, information supplied by the system operator suggests a capacity equivalent to 150-180 days of usage for the city, or in the range of 40-50 mg given an average daily use of approximately 0.28 mgd. The side-channel storage is depleted from daily water use and then refilled periodically. Treatment of river water is a concern, particularly when atrazine levels are high. In some cases, when river water is of poor quality, the side-channel reservoir may not be refilled for two months, and may be drawn down as much as 6 feet during this time.

The Wayne City PWS system was identified by Broeren and Singh (1989) as having potential water supply problems during a severe drought; however, the volume of the side-channel reservoir was believed to have been smaller than that indicated by the system's water operator. Thus, volumetric surveys of the side-channel reservoir and the pool behind the channel dam are needed to provide an accurate estimate of the sustainable yield of the Wayne City system during drought conditions. Water use of the Wayne City system has grown over the last 10 years, from 0.2 to 0.28 mgd, as services have been provided to outlying communities. Wayne City currently supplies the communities of Sims and Keenes and the Western Wayne Water District, which services Johnsonville, Orchardville, Berry, and the Sam Dale Lake Conservation Area.

### **Effluent Discharges to Streams**

Most of the public water used is eventually returned to streams through discharges from wastewater treatment facilities, although many smaller communities use wastewater lagoons that release water to streams only during wet conditions. Because water is discharged to streams from communities supplied by both surface- and groundwater sources, the net impact of water use in the watershed is to increase flows in the stream, except during periods of very low flow. Monthly discharge data were obtained from the Illinois Environmental Protection Agency for all sanitary effluents in the Little Wabash River watershed having an average discharge greater than 50,000 gpd. The frequency of daily discharges for these effluents was estimated using methods described by Knapp (1988, 1990, and 1992). These methods also used data on low flow discharges given in Singh et al. (1988).

Table 12 lists the 23 largest effluent discharges in the Little Wabash River watershed. Appendix B lists the full set of discharge frequency data computed for these 23 discharges and used by the ILSAM.

Facility name	Average discharge (cfs)	Facility name	Average discharge (cfs)

~		Xenia	0.11

# Table 12. Major Effluent Discharges in the Little Wabash River Watershed

# **Characteristics of Observed Streamflows**

# **Streamgaging Records**

There are about 5145 miles of rivers and streams in the Little Wabash River watershed. The status of these rivers and streams is monitored by streamgaging stations, which are established at selected locations and measure the flow of water over a period of time. These measurements provide information on the amount and distribution of surface water passing the stations. These streamflow records may be used to evaluate the impacts of changes in climate, land use, water use, and other factors on the water resources of a river basin.

The U.S. Geological Survey (USGS) has operated seven continuous-discharge streamgages in the Little Wabash River watershed. Table 13 lists these stations, and figure 2

USGS ID	Station name	Drainage area (mi <sup>2</sup> )	RL* (years)	Period of record	
	Continuous Discharge Records

Note: * DI - record longth					

# Table 13. USGS Streamgages in the Little Wabash River Watershed

**Note:** \* RL = record length

gives their locations. Four of these gages are currently active, and three of the four gages are long-term gages having record lengths in excess of 50 years. In addition to the continuousdischarge gages, the USGS has operated four gages that monitor river stage. These stage gages, also identified in table 13, have short records of 12 years or less. Miscellaneous discharge measurements were collected at several of these stage gages in the 1970s, but these measurements were not sufficient to establish rating curves and discharge records for these gages.

# **Human Impacts on Streamflows**

As indicated earlier, the characteristics of streamflow in any moderately developed watershed will, over time, vary from earlier conditions because of a combination of climate variability and the cumulative effect of human activities in the region. Most of the streamgaging records in this region are less than 60 years old, and thus represent hydrologic conditions related to the agricultural landscape of the region in the 20th Century. Climate variability also influences the changes in streamflows from year to year and decade to decade. The major changes to the climate during this century are assumed to occur from natural climatic variability. However, with recent research focusing on global climate change, it is possible that these changes may be shown also to result from human influences.

For several locations in the Little Wabash River watershed, water use and water resource projects have readily definable impacts on streamflows. Five water supply systems at Effingham, Flora, Clay City, Fairfield, and Wayne City withdraw water directly from the Little Wabash River and Skillet Fork, which has an impact on the low flows in these rivers. Treated wastewater discharges from the larger communities in the watershed also have a significant impact on the low flow in their receiving streams. Thus, the net result of the public water supply (withdrawal and effluent return) on low flows may be positive or negative depending on location. The streamflow immediately downstream of the major reservoirs in the watershed has been altered, as these reservoirs attenuate the magnitude of high flows downstream to varying degrees.

# **Streamflow Variability**

# Average Annual Streamflow

The average annual amount of precipitation in the Little Wabash River watershed is approximately 42 inches and ranges from about 39 inches at the northern edge of the region to more than 45 inches at the southern edge. Of this water, about 70 percent eventually returns to the atmosphere through evapotranspiration. Most of the remaining 30 percent ultimately flows to streams by way of runoff after precipitation events or from the more gradual seepage of water stored in the soil and shallow groundwater. The average amount of streamflow during the last half of this century has been approximately 12 inches This represents an average flow rate of approximately 0.9 cubic feet per second (cfs) per square mile of drainage area. The average annual streamflow varies geographically across the region, ranging from 10 inches at the northern edge of the watershed to almost 14 inches at the southern edge.

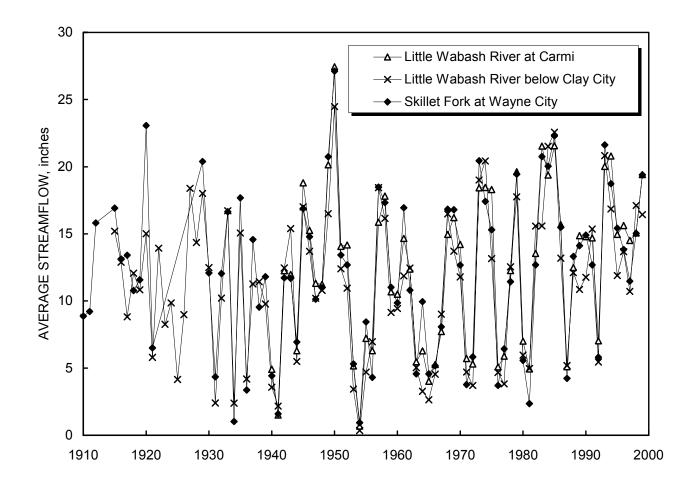

Figure 5. Average annual streamflow for long-term gaging records, Little Wabash River watershed, 1910-2000

Figure 5 shows the annual series of average streamflow for the three longest gaging records in the watershed: Little Wabash River at Carmi, Little Wabash River below Clay City, and Skillet Fork at Wayne City. Flows are presented in units of inches of runoff over each gage's subwatershed. These plots show that average streamflow in the watershed can vary greatly from year to year and between decades. The statistical trends in these flows are examined in the "Streamflow Trends" section of this report.

Figure 5 shows that there is usually a considerable similarity in the total annual flows in the watershed. However, for gages on smaller watershed areas (figure 6), there can be some geographic variability in the average annual flows, which is particularly noticeable in the periods 1963-1970 and 1983-1990. The gage on Horse Creek near Keenes typically shows the highest annual runoff, whereas the Little Wabash River near Effingham typically shows the lowest annual runoff.

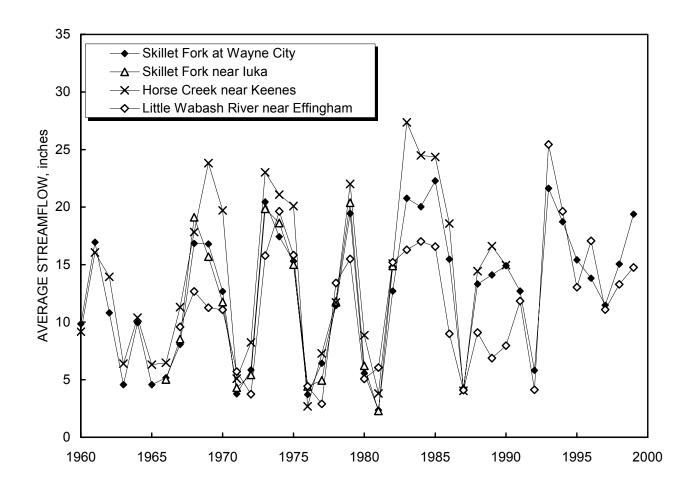

Figure 6. Average annual streamflow for selected watersheds, Little Wabash River watershed, 1960-2000

### Monthly Streamflow

As with all other locations in Illinois, streams in the Little Wabash River watershed display a well-defined seasonal cycle. Figure 7 shows the monthly probability of flows for the Little Wabash River below Clay City. Three levels of flow probability are given: 50 percent flow (medium flow), 10 percent flow (high flow), and 90 percent flow (low flow). The 10 percent flow is exceeded only 10 percent of the time during that month. In contrast, the 90 percent flow is exceeded 90 percent of the time, and thus represents the expected low flow conditions in the stream. This figure shows that the average flow in any month can vary considerably from the long-term median condition. For example, the highest 10 percent of the flows can be more than 10 times the median flow for any month. Flows are normally expected to be greatest during the spring months, March-May, and then decline until the lowest flow conditions in or around October.

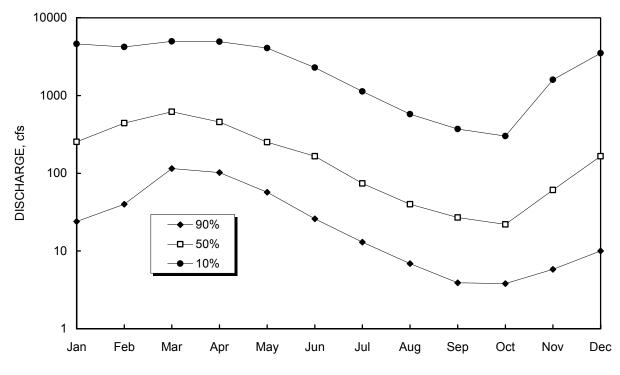

Figure 7. Probability of exceedence for monthly flows, Little Wabash River below Clay City

#### Variations in Daily Streamflows

Figure 8 plots the flow duration curves for six gaging records in the watershed: Little Wabash River at Carmi, Little Wabash River below Clay City, Skillet Fork at Wayne City, Skillet Fork near Iuka, Horse Creek near Keenes, and Little Wabash River near Effingham. The flow duration curve provides an estimate of the frequency with which the given flows are exceeded. As described earlier, the flow duration represents the percentage of time at which the flow is greater than a given rate; for example, the 90-percent flow is exceeded 90 percent of the time for the period of record, and thus represents the expected low flow conditions in the stream. The magnitude of the flows at each gaging location are different because of varying watershed size. For example, the flows for the Little Wabash River at Carmi convey the runoff for almost the entire Little Wabash River watershed (3102 square miles), and thus flows are much higher than at any of the other gage locations, in particular the Horse Creek gage where the drainage area is only 97 square miles.

Variations in the overall shapes of the flow duration curves often point to either regional differences in the hydrology of the streams or human impacts on streamflows. As can be seen in figure 8, the flow duration curves for most of the gaging records have a very similar shape and plot as nearly parallel lines. The gradient in the flow duration curve is somewhat steeper for smaller streams than for larger rivers, which is typical for any region, and several smaller streams have zero flow during extremely dry periods. The flow duration

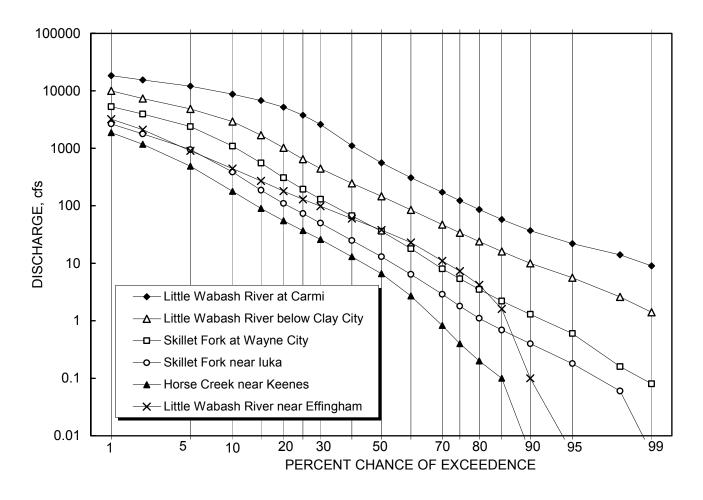

Figure 8. Flow duration probability of daily flows for gaging stations in the Little Wabash River Watershed

curve for the Little Wabash River near Effingham is unique in that it does not act in a similar manner to the other curves. Three factors contribute to the difference in the flow duration curve for the Effingham gage: 1) the northern part of the watershed upstream of Effingham is part of the Bloomington Ridged Plain, a physiographic region that has higher soil permeability and typically has a smaller variability between high and low flow conditions; 2) three PWS reservoirs have an impact on the upstream watershed; and 3) water withdrawn from the Little Wabash River one mile upstream of the gage reduces the magnitude of low flows.

### High Flows

Figure 9 shows the annual series of 1-day high flows for the two longest gaging records in the watershed: Little Wabash River below Clay City and Skillet Fork at Wayne City. The 1-day high flow is the highest average flow over one calendar day during each water year, and the high flow amount is similar to but slightly lower than the peak discharge for that day for both gages. Figure 9 shows that the high flow events for all stations had noticeably low magnitudes during the drought periods of the 1930s and 1950s. The greatest flood event for both gages occurred during May 1961. The two highest flows on the Skillet

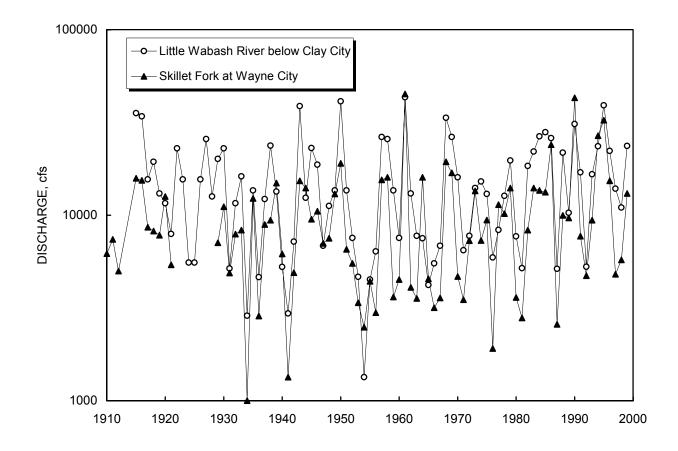

Figure 9. Annual series of 1-day high flows for long-term gaging records in the Little Wabash River watershed, 1910-2000

Fork, 1961 and 1990, are substantially greater any other event in that station's record. Examination of the 1-day high flows for the Little Wabash River below Clay City indicates little change in high flows over that station's 85-year period of record.

## Low Flows

Figure 10 shows the annual series of 7-day low flows for the Little Wabash River at Carmi and below Clay City. The low flow values for Clay City do not show any significant long-term change over its 85-year period of record, although low flows are noticeably lower for several periods between 1930 and the early 1960s. The low flows for Carmi have a higher magnitude than the flows at the Clay City gage, but generally follow a similar pattern. The 7-day low flows in the Skillet Fork at Wayne City, not shown, are less than 1 cfs for most years on record. In the past 12 years there has been a noticeable increase in the frequency of occurrence of zero flows at the Skillet Fork gage, which may be related to an increase in withdrawals from the Wayne City PWS located directly upstream of the gage.

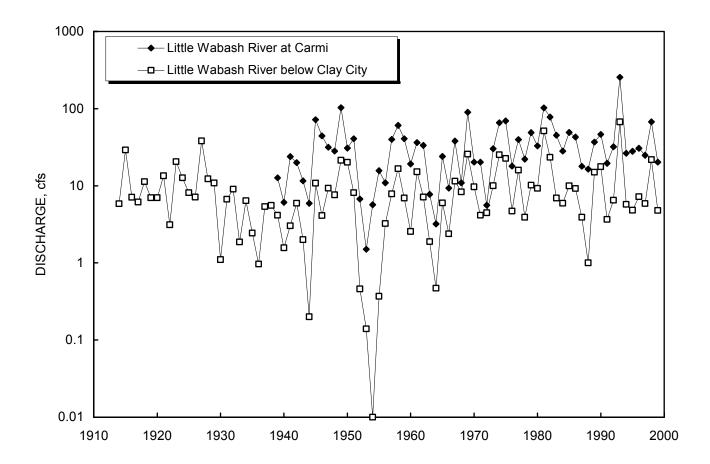

Figure 10. Annual series of 7-day low flows for long-term gaging records in the Little Wabash River watershed, 1910-2000

#### Streamflow Trends

An examination of figure 5 indicates that the Little Wabash River watershed has experienced stretches of above and below average streamflows. For example, the annual flows during much of the decade of the 1930s and the period 1953-1966 were well below the long-term average of 12 inches. In contrast, flows during 1915-1929 and 1968-1986 were well above the long-term average. During each period, locations in the Little Wabash River watershed have experienced flows in the range of 10 to 25 percent different than their long-term average streamflow. These changes in average streamflow can be attributed to coincident changes in precipitation.

Trend correlation statistics were estimated for the annual flow records of the three gaging stations having long-term records (greater than 50 years): Little Wabash River at Carmi, Little Wabash River below Clay City, and Skillet Fork at Wayne City. Table 14 presents these correlation statistics. The Kendall trend statistic was used to provide an indicator of the increase or decrease in the flow values. A Kendall correlation of 1.0 indicates an absolute increasing trend, with each year having a higher flow than the previous year. A Kendall correlation of -1.0 indicates an absolute decreasing trend, and a Kendall

		Kendall trend correlation						
		Average	High	Low				
Station name analyzed	Years							
Little Wabash River below Clay City	1914-1999	0.087	0.066	0.052				
Skillet Fork at Wayne City	1914-1999	0.081	0.071	-0.068				
Little Wabash River below Clay City	1939-1999	0.150	0.167	0.196				
Skillet Fork at Wayne City	1939-1999	0.140	0.116	-0.030				
Little Wabash River at Carmi	1939-1999	0.185	0.194	0.170				
Little Wabash River below Clay City	1970-1999	0.122	0.159	-0.103				
Skillet Fork at Wayne City	1970-1999	0.094	0.142	-0.251				
Little Wabash River at Carmi	1970-1999	0.140	0.147	0.104				

#### Table 14. Trend Correlations for Annual Average, High, and Low Flows

correlation of 0.0 indicates no trend. The statistical significance of a trend correlation depends in part on the length of the record being analyzed. With a 50-year record, correlation values greater than 0.16 or less than -0.16 indicate a statistically significant trend, one that can be declared with a 90 percent level of confidence. The level of confidence with which a trend can be declared increases as the absolute value of the correlation increases. To establish statistical significance, shorter records require a higher correlation value, and longer records do not need as high a correlation value.

The trend coefficients in Table 14 were computed for three periods of record: 1914-1999, 1939-1999, and 1970-1999. These different periods were chosen to illustrate the effect that the period of record has on the perception of hydrologic trends, and in part are influenced by the period of record at gages in the watershed. The magnitude of the trend coefficients are generally highest when computed over the period 1939-1999, i.e., a period that starts during dry hydrologic conditions (the droughts of the 1930s-1950s) and ends during the 1990s, a period that represents generally wet hydrologic conditions. When trend coefficients are computed over the shorter period from 1970-1999, the presence of a hydrologic trend is generally less apparent. It is clear, however, that the low flows on the Skillet Fork at Wayne City have decreased during this latter period. Most importantly, there appears to be little trend in streamflows when computed over the long-term conditions from 1914-1999.

#### Factors in Estimating Flow Frequency at Gaged Sites

The flow observed at a gaging station represents the cumulative effects of 1) the unaltered or "virgin" hydrologic conditions as influenced primarily by weather and climate phenomena as well as the topography, hydrogeology, and prevailing land-use conditions in the watershed, and 2) modifications to the flow conditions by human activity. Changes in the streamflows over time can occur as a result of climatic variability or from human impacts. For this reason, the flow frequency computed directly from a streamgaging record may not always be indicative of the present flow regime on a stream, and it may not be directly comparable to flows measured at different periods of time or at different locations.

#### Selecting a Representative Period for Estimating Long-Term Conditions

As described earlier, streamflows can show sizable variation, not only between individual years but also between decades. It is possible that a given 10- or 20-year period of gaging primarily may reflect wet or dry conditions within the watershed, and not totally reflect the full range of expected hydrologic conditions over time. Thus, the years included in a streamgage record have a significant impact on the estimation of flow frequency at that gage. A primary consideration in the development of flow estimates for ILSAM is that a consistent relationship be maintained between different locations. For this reason, it is necessary to define a base period, representative of long-term flow conditions, to which frequency estimates can be related. Considerations include both: 1) finding a base period that includes a representative number of dry and wet hydrologic conditions, and 2) finding a period for which many stations have complete records.

In previous studies, estimates of long-term flow frequency have been developed using a general base period from 1948 to the present. The purpose of selecting this range of years was to provide a base period that both includes both a large number of years of record and a large number of active gaging records, in essence trying to maximize the product of the record length and number of gages.

Figure 11 shows the relationship between the number of years of record and the number of coincident gaging years for streamgages in southern Illinois. For example, for the 51 years from 1948 to 1999, there were nine active gages in the region, yielding a coincident set of 459 gaging years. (This estimate does not include five gages on the Big Muddy and Kaskaskia Rivers that experienced significant flow modifications during this period from large flood control reservoirs.) For the 47-year period, 1952-1999, there were 12 active gages yielding 564 coincident years of gaging record, the maximum number for the gages in southern Illinois. The 28-year period (1971-1999), with 20 active gages, has 560 coincident years. In comparing the 1971-1999 and 1952-1999 periods, there is a tradeoff between length of years (time) versus number of gages (spatial coverage). However, the 1971-1999 period does not contain periods of severe drought, which is a weakness for estimating low-flow frequency. The 47-year period is similar to the base period beginning in 1948 used in developing the ILSAM for other regions of the State, and was adopted in this study to maintain continuity with these previous studies.

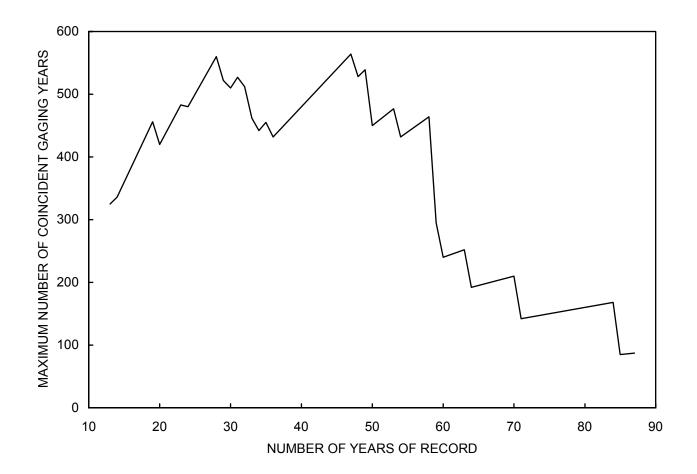

Figure 11. Relationship between period of record and total number of coincident gaging years in southern Illinois

#### **Record Extension Techniques**

Many streamgaging stations, particularly those on smaller streams, have periods of record that are shorter than the base period of 1952-1999. To provide consistent flow frequency estimates throughout the Little Wabash River watershed, it was necessary to estimate the long-term flow conditions at short-term gaging records using some type of record-extension technique. In developing flow frequencies in previous ILSAM studies, a process called a frequency adjustment or frequency shift was used to estimate long-term flow frequencies. This method requires the use of a nearby long-term gaging record, called an index station, which is used to related the differences in flow conditions for the short-term versus the longer base period. Details on this method are presented in Knapp (1988, 1990). This frequency adjustment technique has been compared to the MOVE.1 technique (Hirsch, 1982), which is more commonly used for record extension. These comparisons indicate that the frequency shift method generally provides a more accurate estimate of the long-term flow frequency than MOVE.1 when using shorter gaging records in Illinois.

#### **Evaluating Human Modifications to Streamflows**

When ILSAM was initially developed, the evaluation of virgin and present flows for a particular gaging record required simulating a time series associated with both the virgin flow and the quantity of flow modification relating to human impacts. When dealing with a reservoir, for example, this included developing a daily flow-routing model of the reservoir, and computing reservoir outflows from either simulated or historical inflows. Under conditions when flow modifications have changed significantly over time, it is sometimes still necessary to follow such an approach. But based on a number of simulations of this type, empirical algorithms were developed for use in ILSAM to estimate the impact of such modifications on flows at ungaged sites. These algorithms, which are coded within ILSAM, have in themselves become useful in estimating the impacts of flow modifications when evaluating virgin and present flows at gaging locations. In this type of procedure, an existing modification located upstream can be input into the model to estimate the downstream impact on streamflows at a gaging location. An iterative process can then be used to compute the virgin and present flow sat that site.

The algorithms developed for use in ILSAM to estimate the impacts of flow modifications have been described in several previous reports. The ILSAM reports that are most comprehensive in their discussion of these techniques are Knapp (1988, 1990), and the reader is referred to these studies for details. Examples of these algorithms include methods for estimating: the impacts of reservoirs on downstream flows, variability of effluent discharges during low flow conditions, reduction of low flows when effluents are discharged into dry stream beds, and the impact of seasonal flow modification on the annual flow frequency.

#### Value of Gaging Data in Defining Flow Conditions in the Watershed

There are four active gages in the Little Wabash River watershed, or roughly one gage for every 800 square miles of drainage area. The southeastern portion of Illinois, including the Little Wabash River watershed, has the lowest density of streamgages in the state, but most of the existing gages have long periods of record that aid in determining long-term flow conditions in the watershed. Withdrawals for water supply have some degree of impact on the streamflows at all existing gages, and provide valuable information for quantifying these impacts. In general, the region would benefit from additional active gages on smaller watersheds so that the regional methods to estimate flow conditions at ungaged sites do not have to rely upon gages on smaller streams located outside the region or on older short-term gaging records that may not accurately reflect present or long-term conditions. In addition, for evaluating the yield of the current water supply, low flow measurements during drought years would be useful on the Little Wabash River near the Fairfield withdrawal, in the vicinity of Golden Gate.

#### Factors in Estimating Flow Frequency at Ungaged Sites

The ILSAM estimates flow conditions at ungaged sites through the use of three types of information: 1) a set of regional equations to estimate unaltered or "virgin" flow conditions at the ungaged site, 2) data on the extent of flow modification upstream of the site, and 3) a collection of model algorithms used to estimate the impact of flow modifications on downstream locations.

Appendices A and B provide data on the human modifications for use in evaluating impacts on flows at ungaged sites. Among the streamflow information listed in Appendix A are the locations and flow modifications related to the major reservoirs in the watershed. Appendix B provides the quantity of flow modification associated with the effluent discharges and water withdrawals within the watershed. Previous ILSAM reports (Knapp, 1988, 1990) describe the algorithms and techniques used to extend these impacts further downstream. As indicated earlier, the evaluation of flow modifications does not include those major changes to the watershed hydrology in the 1800s and early 1900s caused by cultivation and major drainage modifications. Nor are hydrologic changes from recent drainage or agricultural management practices considered, since there is little data from which to explicitly evaluate these impacts. Thus, the virgin flow, as estimated in this report, essentially reflects the unaltered hydrology associated with the climate and general rural land use conditions that existed in the watershed throughout the mid- and late-1900s.

Most locations in the Little Wabash River watershed, particularly those on minor streams, do not have significant modification to their flows. Thus, the development of an appropriate set of regional equations represents the most dominant factor in estimating flows at ungaged sites. The remainder of this section focuses on the development and application of these equations.

#### **Regional Equations for Estimating Virgin Flow at Ungaged Sites**

The regional equations used to estimate unaltered flow conditions are based on a regression analysis of streamgage records within geographic regions that are expected to have similar streamflow characteristics. In previous ILSAM studies, the physiographic divisions established by Leighton et al. (1948) were used to define the geographic areas for which regional equations were developed. Within each region, three watershed characteristics, drainage area, soil permeability, and average annual net precipitation (precipitation minus evapotranspiration), were independent variables used in the regional equations to describe the variation in streamflow characteristics.

To develop and apply the regional flow equations to the Little Wabash River watershed, it was necessary to develop a database of watershed characteristics for all streams within the watershed. A database table, termed the NETWORK table, includes information on drainage area, soil permeability, and average annual net precipitation for approximately 800 stream locations within the watershed. Drainage areas were measured for all locations, data from county soil surveys and statewide soil association maps were used to estimate the average permeability of the soil substrate, and long-term precipitation and streamflow records were used to estimate the net precipitation within the watershed upstream of each location. The resulting NETWORK table is included in the relational database developed for the Little Wabash River ILSAM model, and the values in the table are listed in appendix C. The two major physiographic divisions of the Little Wabash River watershed are the Springfield Plain and the Mt. Vernon Hill Country. These are also predominant physiographic regions in the Kaskaskia River watershed, which was analyzed in a previous study (Knapp, 1990). During this earlier study, one set of regional flow equations was found to be applicable to both physiographic divisions. For the current study, the equations were updated to take into account 13 years of additional flow data that are available from gaging stations throughout the two physiographic regions, and this equation is considered to be applicable for all stream locations within the Little Wabash River watershed.

A total of 28 streamgaging records from watersheds located within the Springfield Plain and Mt. Vernon Hill Country were examined as potential input for developing the updated set of regional equations. Each gage examined contains a minimum of 22 years of record and flow conditions that have had relatively little or no impact from upstream modification. Five gaging stations in the far northwestern portion of the Springfield Plain, in the vicinity of Macoupin, Greene, Morgan, and Sangamon Counties, were dropped from consideration after it was observed that their flow characteristics were somewhat different than those at the remaining gages, and atypical of flow conditions in the Little Wabash River watershed. Table 15 identifies the remaining 23 gages used in the analysis. The flow at one of the stations, the Little Wabash River near Effingham, which is affected by upstream withdrawals, was not used in developing equations for low flow conditions. Two gaging records for Cahokia Creek at Edwardsville and Hurricane Creek near Mulberry Grove also were not used for evaluating low flow frequency because their period of record did not contain any significant periods of low flow or drought as compared to the other gaging locations.

In the development of the regional equations, the relationship between the streamflow quantity and watershed characteristics follows the following form:

$$Q_{x} = \max \{ Q_{mean} [ a + b K + c DA ] - 0.05, 0 \}$$
(1)

where  $Q_x$  (cfs) is any individual flow parameter estimated by the model;  $Q_{mean}$  (cfs) is the annual mean flow at the location of interest; K (inches per hour) is the average subsoil permeability of the watershed; and DA (square miles) is the total drainage area of the watershed. The constant -0.05 is used to interpret very low, nonzero flows as essentially representing dry zero-flow conditions. The annual mean flow is determined from estimates of the average annual values for precipitation (inches) and evapotranspiration (inches) over the watershed:

$$Q_{mean} = 0.0738 \text{ DA} (P - ET)$$
 (2)

The difference between average annual precipitation and evapotranspiration, P - ET, has been computed for all stream locations in the Little Wabash River watershed, and these are included in the NETWORK table of the ILSAM database and listed in appendix D. This difference is termed the average annual excess precipitation.

The form of equation 1 and the independent variables used in that equation were developed in previous ILSAM regional studies for various parts of the State, including the Kaskaskia River watershed bordering the Little Wabash River watershed. Several of these previous studies investigated the use of other watershed factors such as channel slope and land slope for the regional regression equations, but provided little or no improvement in

#### Table 15. USGS Streamgage Records Used for Developing Regional Equations

**Note:** \* RL = record length.

the standard error of the regression analysis. No additional attempt was made in the present study to identify other additional watershed characteristics that could be useful as independent variables in equation 1.

For each flow variable, least squares regression was used to compute the values of coefficients a, b, and c in equation 1. The equations developed using this approach, while they produce minimal error, do not always maintain a consistent relationship for each and every combination of watershed characteristics. For example, in some cases it is possible to specify a drainage area and subsoil permeability in which the  $Q_{99}$  flow duration estimated by the equations becomes greater than the estimated  $Q_{98}$ , thus violating the definitions of these flow values. For this reason, the equations that were developed using the least squares approach were each examined to identify potential situations where the results of the model may produce inconsistent estimates of flow frequency. In cases where a potential inconsistency exists, equation coefficients were adjusted to avoid the inconsistency. This type of adjustment produces an equation that is "not quite least squares," but still has low error while producing flow duration curves and low flow frequency estimates that are consistent, i.e., make sense both hydrologically and statistically.

Appendix D lists the resulting coefficients developed for each of the 154 flow parameters used in the Little Wabash ILSAM. Also shown in appendix D is a coefficient of error associated with these equations. To compute the error of a particular flow parameter in units of cfs, the coefficient of error,  $c_e$ , is multiplied by the mean flow rate in cfs at the location of interest. The error in the regional equations is generally in the range of 10 to 25 percent, but it is larger for low flow conditions. An example of the application of the equations is given below. Results are applicable to locations from 10 to 1000 square miles.

#### **Application of Regression Equations**

The application of the equations is illustrated by the following example in which various annual flow duration statistics are estimated for the Fox River, a tributary to the Little Wabash River, at a location near the Olney sanitary treatment plant. The watershed for this location has the following characteristics:

Drainage area = 97.6 square miles Average soil permeability = 0.37 inch per hour Average annual excess precipitation (P - ET) = 11.89 inches Physiographic region: Springfield Plain

The following estimates of the annual flow duration are computed:  $Q_{98}$ ,  $Q_{90}$ ,  $Q_{75}$ ,  $Q_{50}$ ,  $Q_{25}$ ,  $Q_{10}$ , and  $Q_{02}$ . The virgin flow coefficients from appendix D are used in the following computations:

$$Q_{\text{mean}} = 0.0738 \ (97.6) \ (11.89) = 85.6 \ \text{cfs}$$

$$Q_{98} = 85.6 \ [-0.00174 + 0.0000068 \ (97.6) + 0.00190 \ (0.37)] - 0.05, 0\}$$

$$= -0.08 \ \text{cfs}, \text{ or effectively } 0.0 \ \text{cfs}$$

$$Q_{90} = 85.6 \ [-0.00180 + 0.0000211 \ (97.6) + 0.00338 \ (0.37)] - 0.05 = 0.08 \ \text{cfs}$$

$$\begin{aligned} Q_{75} &= 85.6 \ [0.00227 + 0.0000489 \ (97.6) + 0.01802 \ (0.37)] - 0.05 = 1.12 \ cfs \\ Q_{50} &= 85.6 \ [0.03994 + 0.000124 \ (97.6) + 0.09961 \ (0.37)] - 0.05 = 7.6 \ cfs \\ Q_{25} &= 85.6 \ [0.29886 + 0.000381 \ (97.6) + 0.20408 \ (0.37)] - 0.05 = 35 \ cfs \\ Q_{10} &= 85.6 \ [1.80311 + 0.001011 \ (97.6) - 0.10537 \ (0.37)] - 0.05 = 159 \ cfs \\ Q_{02} &= 85.6 \ [11.03862 - 0.00311 \ (97.6) - 0.4448 \ (0.37)] - 0.05 = 905 \ cfs \end{aligned}$$

The virgin flow estimated by the equations for an ungaged site will be adjusted by the ILSAM if there is a gaging station on the same stream at which virgin flow is estimated directly from the gaging record. The technique used in this adjustment is described in previous ILSAM reports (Knapp, 1988, 1990). This adjustment is needed to blend the information at the gage site with the results of the regional equations, and thus maintain a smooth transition between the two types of estimates.

#### **Error in Regression Model**

The regression relationship between the flow and watershed characteristics explains a high amount of the flow variance between gaging stations in the sample. However, there still can be considerable variation in flows across the watershed and uncertainties in the flow estimate, particularly for smaller watersheds. The standard error of estimate for the virgin flow equations ( $s_e$ ), in cfs, is estimated as the product of the coefficient of error given in appendix D ( $c_e$ ) and the computed mean flow at the point of interest (Q<sub>mean</sub>):

$$\mathbf{s}_{\mathrm{e}} = \mathbf{c}_{\mathrm{e}} \, \mathbf{Q}_{\mathrm{mean}} \tag{3}$$

This method of estimating the standard error is derived through the form of the regression equation (equation 1), with  $c_e$  being a standard term for coefficient of error. The percentage of error can be computed as the standard error of estimate divided by the estimated flow for a given parameter. The standard error in computing  $Q_{mean}$  (using equation 2) is 6.8 percent.

Two examples of the computation of the standard error of estimate for the above application example are provided on the following page, along with the range of flow values contained within one standard deviation from the computed estimate of the flow parameter. The first example is for the Fox River near the Olney sanitary treatment plant, and the second example is for Big Muddy Creek at its mouth. The drainage area of the Big Muddy Creek site is over three times larger than that for the Fox River site, and has a mean flow of 271 cfs.

The absolute value of the error increases as the size of the watershed increases and as the flow amount increases, i.e., being greater for high flow conditions than for low flow conditions. However, the percentage error acts in exactly the opposite manner, being smaller for larger watersheds and substantially smaller for high flows than for low flows.

Note that there is typically a large percentage error when the estimated flow approaches 0.0. Thus, in the examples above, this error of estimate exceeds 100 percent for extremely low flow conditions. However, the percentage error of estimate becomes much less for larger flows, and is approximately 10 percent for the  $Q_{02}$  flow parameter.

Flow parameter	Flow estimate	Standard error of estimate	Range
Q <sub>98</sub>	0.00	$s_e = 85.6 * 0.001406 = 0.12 \text{ cfs}$	-0.20 to 0.04 cfs
Q90	0.08	$s_e = 85.6 * 0.004322 = 0.37 \text{ cfs}$	-0.29 to 0.45 cfs
Q75	1.12	$s_e = 85.6 * 0.01344 = 1.15 \text{ cfs}$	-0.03 to 2.27 cfs
Q50	7.6	$s_e = 85.6 * 0.04112 = 3.5 \text{ cfs}$	4.1 to 11.1 cfs
Q <sub>25</sub>	35.	$s_e = 85.6 * 0.1278 = 11 \text{ cfs}$	24 to 46 cfs
Q <sub>10</sub>	159.	$s_e = 85.6 * 0.3893 = 33 \text{ cfs}$	126 to 192 cfs
Q <sub>02</sub>	905.	$s_e = 85.6 * 1.015 = 87 \text{ cfs}$	818 to 992 cfs

Example 1. Fox River near Olney treatment plant (drainage area = 97.6 square miles)

Example 2.	<b>Big Muddy</b>	Creek at mouth	(drainage area =	340 square miles)

Flow parameter	Flow estimate	Standard error of estimate	Range
Q <sub>98</sub>	0.27	$s_e = 271 * 0.001406 = 0.12 \text{ cfs}$	-0.11 to 0.65 cfs
Q90	1.63	$s_e = 271 * 0.004322 = 1.17 \text{ cfs}$	0.46 to 2.8 cfs
Q75	6.7	$s_e = 271 * 0.01344 = 3.6 \text{ cfs}$	3.1 to 10.3 cfs

#### **Estimation of Present Flow**

The estimation of present flow for a given ungaged site includes both the estimate of virgin flow and an estimate of the cumulative impact of all flow modifications located upstream from that site. All modifications located upstream of any site are represented in the model, either explicitly by way of their location on the stream or through summary statistics that, for specific locations called control points, estimate the cumulative impacts of all upstream modification. The estimation of present flow works in an upstream to downstream direction, starting with the flow modifications that exist most upstream of the site of interest. As indicated earlier, the ILSAM has a collection of algorithms for evaluating present flow conditions. These algorithms are described in several previous reports Knapp (1988, 1990) and have been briefly mentioned in the previous section of this report.

#### **Model Operation**

The current version of the ILSAM was developed to operate on a personal computer having a Microsoft Windows 95/98/2000/NT operating system. The model user is expected to identify the stream and location on the stream for which flow statistics are to be computed. Appendix C provides a list of the streams within the Little Wabash River watershed and the locations on these streams identified by river mile. The model can calculate streamflow statistics for existing conditions in the watershed. The model user also may input a description of a potential or hypothetical water resources project to identify the potential impact of such an additional flow modification.

Appendix C also contains a table of watershed characteristics for more than 800 locations in the watershed. The model uses this table to identify the watershed characteristics pertinent to the location selected by the model user. These characteristics are used in a set of regional equations to estimate unaltered flow conditions at any ungaged site in the watershed. These equations are described in the previous section of this report ("Defining Virgin and Present Flow Conditions at Ungaged Sites") and are presented in appendix D.

The model searches for information on streamflow modifications that are located upstream of the point selected by the model user, and then estimates the cumulative impact of these flow modifications. The model supplies two basic data components from which to compute the impact of these flow modifications and the subsequent streamflow quantity. The first data component is a set of computed flows for selected locations (control points) in the watershed, which include the calculated cumulative impacts of all modifications upstream of that site, given in appendix A. The impact of reservoirs on streamflow is presented in this set of data. The second data component is a set of data on effluent discharges and water withdrawals in the watershed, given in appendix B. Additional algorithms are included in the model to estimate downstream impacts from specific types of flow modifications.

Every step in the computation of flow conditions includes some amount of uncertainty. Measurement error in streamgaging, and the resulting estimate of daily flows, is generally considered to be in the range of 5 to 15 percent, depending on the quality of the gaging location. Additional uncertainties are associated in the processing of hydrologic information for the model, including 1) the record extension techniques used for short periods of record, 2) errors in estimating the frequency of infrequent events such as low flows, 3) the separation of the gaging record into virgin flow conditions and the impact of flow modifications, and 4) the algorithms that estimate downstream impacts of the various types of flow modifications. Only the error in the regional flow equations, given in appendix D, is readily quantifiable and generally applicable to all locations within the basin. Because the estimated error in developing these regional equations also encompasses many of the other errors listed above, it is reasonable to accept them as a reasonable comprehensive error for the entire process of flow estimation.

#### Conclusions

This report describes some of the basic hydrologic analyses used to identify the expected long-term virgin and present flow conditions at gaged and ungaged locations throughout the Little Wabash River watershed. The long-term flow conditions are presented as streamflow frequency statistics that describe either the percent chance that a given flow will be exceeded or the recurrence interval, in years, defining how frequency statistics that the model estimates is given in the "Introduction" of this report.

This study has produced data sets of water use quantity, streamflow quantity, and watershed information, which are developed in the form of databases for use with the current Windows-based version of the Illinois Streamflow Assessment Model (ILSAM). Most of the basic data used by ILSAM are included in the appendices.

The proper prediction of expected flow conditions in the future will require additional periodic evaluation to account for flow changes that result from either climatic variability or additional human impacts in the watershed. The ability to perform these periodic evaluations will depend in part upon the continued procurement of flow data from streamgaging, particularly from gaging locations that are located to provide the most useful information on regional hydrology.

Note: Streamflow values published by the U.S. Geological Survey ordinarily have three significant digits for values greater than or equal to 100 cfs, and two significant digits for values less than 100 cfs. Additional significant digits have been added to some streamflow frequency estimates in this appendix when used by ILSAM to estimate relative differences in flow values, either between virgin and present flow conditions, or between flows at two different locations. The additional digits do not indicate an improvement in the accuracy of the streamflow estimates.

#### Appendix B. Withdrawals and Effluent Discharges: Location and Estimated 1997 Flow Conditions

Facility	Stream name	Code	Mile
Albion STP	Butter Creek Tributary	BHON	2.8
Altamont South STP	,	BV8	2.0 9.1

#### Appendix C. NETWORK File Describing the Location of Streams, Control Points, Withdrawals, and Discharges in the Little Wabash River Basin

#### List of Stream Names and Associated Codes

Stream name	Code	Stream name	Code
Auxier Creek Drain	BEJG	Fox River	BM
Bear Creek	BENGD	Fulfer Creek	BV6
Bear Creek	BJKPG	Fulton Creek	BEU
Beaver Creek	BEE	Gentry Creek	BMD
Big Creek	BH	Green Creek	BX
Big Creek	BMLC	Grindstone Creek	BC4
Big Creek	BV8	Harper Creek	BHM
Big Mound Drainage Ditch	BEH	Haw Creek	BEG8
Big Muddy Creek	BP	Henry Creek	BXK
Big Muddy Diversion Ditch	BPA	Hog Run Creek	BO
Bills Creek	BYIE	Horse Creek	BEN
Bishop Creek	BU	Hurricane Creek	BPI
Blue Point Creek	BW8	Kennedy-Voris Main Drain	BEGJF
Briar Branch	BI4	Lick Creek	BC
Brush Creek	BEP	Lily Creek	BW2
Brush Creek	BYI	Limekiln Creek	BEB
Buck Creek	BR	Limestone Creek	BPP
Bush Creek	BZ	Limestone Creek	BV6J
Butter Creek	BHO	Little Bishop Creek	BUG
Clay City tributary	BQ	Little Dry Fork	BEKN
Clear Creek	BZ1	Little Fox Creek	BML
Coal Bank Creek	BENO	Little Muddy Creek	BPAK
Conners Branch	BEV2	Little Pond Creek	BH9
Coon Creek	BV8K	Little Salt Creek	BVG
Copperas Creek	BY3	Little Wabash	В
Crooked Creek	BS2	Livergood Creek	BEJ
Deer Creek	BJKC	Long Branch	BMS
Deer Creek Drainage Ditch	BJK	Lost Creek	BED
Dietrich Creek	BUP	Lost Fork	BEW
Dismal Creek	BS9	Lucas Creek	BT
Drake Creek	BYF	Madden Creek	BL7J
Dry Fork	BEK	Main Outlet	BEG
Dums Creek	BEV	Martin Creek	BJKCB
East Branch Green Creek	BXJ	Nickolson Creek	BET
East Fork	BMP	North Mount Erie tributary	BN
Edgewood tributary	BT1	Opossum Creek	BEGT
Elliot Creek	BF	Paddy Creek	BEO6
Elm River Drainage Ditch	BJ	Paintrock Creek	BES
Emma Ditch	BA2	Panther Creek	BS
Endslay Creek	BJKI	Pond Creek	BI
Flanders Creek	BC7	Poplar Creek	BES2
Fourmile Creek	BEL	Prairie Creek	BEE8

#### **Stream Names and Associated Codes Continued**

Stream name	Code	Stream name	Code
Puncheon Creek	BENG	Sugar Creek	BPG
Raccoon Creek	BJKP	Sutton Creek	BEX
Ramsey Creek	BUA	Turkey Creek	BMG
Randolf Drainage Ditch	BE6	Unnamed tributary of Big Muddy Creek	BPW
Rock Branch	BEGJP	Unnamed tributary of Butter Creek	BHON
Salt Creek	BV	Unnamed tributary of Lost Creek	BEDJ
Sandy Creek	BPLK	Unnamed tributary of Pond Creek	BIP
Second Creek	BW	Unnamed tributary of Salt Creek	BVB
Second Creek tributary	BWG	Unnamed tributary of Skillet Fork	BEM
Second Salt Creek	BVS	Village Creek	BK
Seminary Creek	BJKQ	Watson Creek	BEG6
Seven Mile Creek	BEC	Weather Creek	BPL
Sexson Branch	BYM	West Branch	BY
Skillet Fork	BE	West Fork Wet Weather Creek	BPJK
Skillet Fork Lagoon	BEI	West Village Creek	BKLJ
South Fork Beaver Creek	BEEL	Westside Diversion Ditch	BK3
Southern Outlet	BEF	Wet Weather Creek	BPJ
Sugar Creek	BL7	White Feather Creek	BENGO
Sugar Creek	BMJ		

**Note:** Each stream has a unique code. Along the course of a stream it is possible for the stream name to change, but the stream code will not change. To differentiate between two streams that share the same name, use the location descriptions presented in the remainder of this appendix.

#### Watershed Characteristics at Locations of Interest in the Little Wabash River Basin

- DA(u) = Drainage area upstream of location (sq mi)
- DA(d) = Drainage area downstream of location (sq mi)
- = Average subsoil permeability (inches/hr) K
- P-ET = Net excess precipitation for the watershed (inches), defined as average annual precipitation (P) minus evapotranspiration (ET)
- ID = 0 Basic watershed information

  - a Dasic watershed information
    a Tributary inflow
    b Effluent discharge
    c Water supply withdrawal
    c Control point (full set of flow information)
    Reservoir

Region = 1 Bloomington Ridged Plain = 2 Springfield Plain

#### Appendix C. Concluded

#### Notes:

PWS – Public Water Supply Sec. – Section STP – Sanitary Treatment Plant trib. – Tributary WWTP – Wastewater Treatment Plant

#### **Appendix D. Coefficients for Virgin Flow Equations**

The mean flow for a stream location ( $Q_{mean}$ ) is computed as:  $Q_{mean} = 0.0738$  DA (P-ET), where the drainage area (DA) and net excess precipitation (P-ET) are included in the NETWORK file, listed in appendix C.

The flow values for the remaining flow parameters, designated by  $Q_x$ , are computed using the following equation:

 $Q_x = min \{ Q_{mean} [a + b DA + c K] - 0.05, 0 \}$ 

where K is the average soil permeability for the watershed, also included in the NETWORK file (see appendix C), and the coefficients a, b, and c are defined in the following table.
